

1 Dividing integers with *DIV* and *IDIV*

- **DIV** → Divides unsigned numbers.
- **IDIV** → Divides signed numbers.

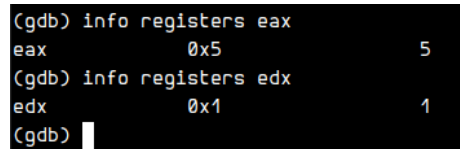

1.1 The **DIV** instruction

Consider the following assembly program:

```
1 section .data
2
3 section .text
4     global _start
5
6     _start:
7         MOV eax, 11
8         MOV ecx, 2
9
10        DIV ecx
11
12        MOV eax, 1
13        INT 80h
```

The **DIV** and **IDIV** instructions work just like the **MUL** and **IMUL**. The **eax** register is automatically used by the **DIV** and **IDIV** instructions.

In the program, **eax** is the dividend and **ecx** is the divisor. The quotient gets stored in **eax** and the remainder gets stored in the register **edx** as shown in the image below:

```
(gdb) info registers eax
eax          0x5          5
(gdb) info registers edx
edx          0x1          1
(gdb) 
```

Figure 1: Values in **eax** and **edx**

1.2 The IDIV instruction

Program:

```
1 section .data
2
3 section .text
4     MOV eax, -6
5     MOV ecx, 2
6
7     IDIV ecx
8
9     MOV eax, 1
10    INT 80h
```

Here, we are dividing a negative number(−6) by 2.

These values are stored in the registers **eax** and **edx**:

```
(gdb) info registers eax
eax             0xfffffffffa      -6
(gdb) si
0x0804900a in _start ()
(gdb) si
0x0804900c in _start ()
(gdb) info registers eax
eax             0x7fffffffdd      2147483645
(gdb) info registers edx
edx             0x0                0
(gdb)
```

Figure 2: Values of **eax** before and after dividing.

So, we can see that **edx** stores the remainder(as we know) which is 0. **eax** stores the the quotient. We can see that **eax** stores a rather larger value, it was expected to store −3.

Now, if we check the value in the sub-register **ax** then we get −3:

```
(gdb) info registers ax
ax             0xffffd            -3
(gdb)
```

Figure 3: −3 in **ax**

Now, we also check in the registers **ah** and **al**. We get the following coutput:

```
(gdb) info registers ah
ah          0xff          -1
(gdb) info registers al
al          0xfd          -3
(gdb) █
```

Figure 4: Values in **ah** and **al**

al stores -3 and **ah** stores -1 .

On converting the value of **eax** to binary we get this:

```
01111111 11111111 11111111 11111101
```

ax stores the last 16-bits, out of those 16-bits, the higher 8-bits are in **ah** and the lower 8-bits are stored in **al**. We also know that 11111101 is -3 .

1.2.1 Comparision

If we take -6 and -3 , this how their binary representation is in 32-bit:

- -6

```
11111111 11111111 11111111 11111010
```

- -3

```
11111111 11111111 11111111 11111101
```

Notice that in the binary representation of -3 and -6 the last 0 in -6 is missing from -3 . It almost looks like -6 was shifted towards the right by 1 bit (but that's not the case here).

Now, when we were debugging our program, **eax** had the following values in it. Binary representation has also been provided (in 32-bit binary):

1st value in **eax**: -6

```
11111111 11111111 11111111 11111010
```

2nd value in **eax**: 2147483645

```
01111111 11111111 11111111 11111101
```

Now, here the second value in **eax** seems to be a result of shifting -6 (the previous value of **eax**) to the right by 1-bit.
